

TITLE OF THE INVENTION

STREAMING METHOD AND SYSTEM FOR EXECUTING THE SAME

BACKGROUND OF THE INVENTION

5 Field of the Invention

[0001] The present invention relates to streaming methods and, more specifically, to a streaming method wherein a server transmits multimedia data over the Internet to a terminal, and the terminal plays back the data while receiving the same.

10

Description of the Background Art

[0002] (Description of Encoding and Compressing Scheme for Multimedia Data, and Buffer Model)

Multimedia data transmitted over the Internet varies in type such as moving pictures, still pictures, audio, text, and data having those multiplexed thereon. To encode and compress the moving pictures, H. 263, MPEG-1, MPEG-2, and MPEG-4 are well known. For the still pictures, well known is JPEG, and for the audio, MPEG audio, G. 729, the list is thus endless.

20 [0003] In the present invention, the main concern is streaming playback. Thus, mainly transmitted here are moving pictures and audio. Herein, described are an MPEG video which is popularly applied to compress the moving pictures, especially an MPEG-1(ISO/IEC 11172) video and an MPEG-2 (ISO/IEC 13818) video which
25 are relatively simple in process.

[0004] The MPEG video has the following two main characteristics to realize data compression with high efficiency. The first characteristic is a compression scheme utilizing intra-frame temporal correlation applied together with a conventional compression scheme utilizing spatial frequency to compress the moving picture data. In data compression by MPEG, frames (pictures) structuring one stream are classified into three types of frames called *I*, *P*, and *B* frames. In more detail, the *I* frame is an Intra-Picture, the *P* frame is a Predictive-Picture which is predicted from information presented in the nearest preceding *I* or *P* frame, and the *B* frame is a Bidirectionally predictive-picture which is predicted from information presented in both the nearest preceding *I* or *P* frame and the nearest following *I* or *P* frame. Among those three type of frames, the *I* frame is the largest, that is, information carried thereby is the largest among all, and the *P* frame, then *B* frame follow. Here, although rather compression algorithm dependent, an information ratio among those frames is about $I:P:B = 4:2:1$. Generally in the MPEG video stream, out of every GOP of 15 frames, *I* frame occurs one, *P* frame four, and *B* frame ten.

[0005] The second characteristic of the MPEG video is to dynamically allocate information on a picture basis according to the complexity of a target image. An MPEG decoder is provided with a decoder buffer, and data is once stored therein before decoding. In this manner, any complex image which is difficult

to compress can be allocated with large amount of information. Not restricting only to MPEG, in any other compression scheme for the moving pictures, the capacity of the general-type decoder buffer is often defined by standards. In MPEG-1 and MPEG-2, the 5 capacity of the standardized-type decoder buffer is 224 KByte. An MPEG encoder thus needs to generate picture data so that the occupancy of the decoder buffer remains within the capacity.

[0006] FIGS. 19A to 19C are diagrams for illustrating a conventional streaming method. Specifically, FIG. 19A shows 10 video frames, FIG. 19B is a diagram schematically showing the change of buffer occupancy, and FIG. 19C is a diagram exemplarily showing the structure of a conventional terminal. In FIG. 19C, the terminal includes a video buffer, a video decoder, an I/P re-order buffer, and a switch. Herein, the video buffer 15 corresponds to the above-described decoder buffer. Any incoming data is once stored in the video buffer, and then decoded by the video decoder. The decoded data then goes through the I/P re-order buffer and the switch, and arranged in temporal order of playback.

20 [0007] In FIG. 19B, the longitudinal axis denotes the buffer occupancy, that is, the data amount stored in the video buffer, and the lateral axis denotes the time. In the drawing, the thick line denotes the temporal change of the buffer occupancy. Further, the slope of the thick line corresponds to the bit rate of the 25 video, and indicates that the data is inputted to the buffer at

a constant rate. The drawing also shows that the buffer occupancy is decreased at constant intervals (33.3667 msec). This is because the data in each video frame is continuously decoded in a constant cycle. Also in the drawing, every intersection point 5 of the diagonal dotted line and the time axis denotes a time when the data in each video frame starts heading for the video buffer. Accordingly, it is known that a frame X in FIG. 19A starts heading for the video buffer at t_1 , and a frame Y at t_2 .

[0008] In FIGS. 19A and 19B, the length of time from t_1 to a 10 time when decoding is first performed (in the drawing, a point at which the thick line first drops) is generally referred to as a time vbv_delay. Decoding is performed immediately after the video buffer being filled. Therefore, the time vbv_delay usually denotes a length of time for the video buffer of 224 KByte to be 15 full from video input. That is, denoted thereby is an initial delay time (latency time to access a specific frame) from video input to video playback by the decoder.

[0009] In the case that the frame Y in FIG. 19A is a complex 20 image, the frame Y includes large amount of information. Thus, as shown in FIG. 19B, data transfer to the video buffer needs to be started earlier (t_2 in the drawing) than the decoding time for the frame Y (t_3). Note that, no matter how complex the image of the frame Y is, the available buffer occupancy remains within 224 KByte.

25 [0010] If data transfer to the video buffer is so performed

as to maintain such change of buffer occupancy as shown in FIG. 19B, MPEG standard assures that streaming is not disturbed due to underflow and overflow of the video buffer.

[0011] (Description of Reception Buffer for Transfer Jitter
5 Absorption on Network)

As shown in FIG. 20, in a system where a server 201 and a terminal 202 are connected to each other through a network 203, a transfer rate fluctuates when MPEG data in a storage 210 is distributed. This fluctuation is due to a time for packet 10 assembly in a generation module 211, a time for transfer procedure in network devices 204 and 205, a transfer delay time due to congestion on the network 203, for example. Thus, actually, the change of buffer occupancy shown in FIG. 19B cannot be maintained. As a method for reducing and absorbing such fluctuation of the 15 transfer rate (transfer jitter), a content of the encoding rate sufficiently smaller than that of the bandwidth of the network is to be transferred. However, from a viewpoint of efficiently utilizing the network resource to provide high-quality video and audio, this method is not considered appropriate. Therefore, 20 applied generally is a method for always transferring data a little ahead of time, and if data transfer is delayed, data shortage is compensated. In this case, the network devices 204 and 205 are provided with transmission and reception buffers 206 and 207, respectively.

25 [0012] Here, providing the reception buffer 207 on the

terminal 202 side means approximately the same as increasing the capacity of a decoder buffer 208 from the standardized 224 KByte by the capacity of the reception buffer 207. For comparison, FIGS. 21A and 21B show the change of buffer occupancy before and after 5 the reception buffer 207 being included. Here, FIG. 21A is the same as FIG. 19B.

[0013] By adding the reception buffer 207, the buffer capacity is increased, and the change of buffer occupancy looks as shown in FIG. 21B. Accordingly, even if the transfer rate of the network 10 is decreased, the buffer will not underflow. On the other hand, the time vbv_delay is lengthened by a time corresponding to the capacity of the reception buffer 207. As a result, the starting time for decoding in a decoder 209 and the starting time for playback in a playback device 212 are both delayed. That is, the 15 time to access a specific frame takes longer by the time taken for data storage in the reception buffer 207.

[0014] As is known from the above, in a network environment such as small-scale LAN where credibility and transmission speed are assured, when the multimedia data such as MPEG data is 20 subjected to streaming playback, streaming playback may not be distributed due to underflow and overflow of the decoder buffer. This is basically true as long as the system is so designed as to keep the initial delay time (vbv_delay) at playback specified by codec specifications and the change of decoder buffer 25 occupancy.

[0015] However, in the wide area network such as the Internet, the transfer jitter resulted in fluctuation of transmission characteristics of the transmission path is too large to ignore. Therefore, together with the decoder buffer (vbv buffer) within 5 the codec specifications, the conventional terminal 202 often includes another buffer as the reception buffer 207 of FIG. 20 for transfer jitter absorption. If this is the case, however, another problem arises.

[0016] The capacity of such buffer included in the terminal 10 for jitter absorption generally varies depending on the device type. Therefore, even if data is distributed under the same condition, the device with large buffer capacity can perform streaming playback with no problem, but the device with small buffer capacity cannot absorb the jitter enough and thus fails 15 in streaming playback.

[0017] To solve this problem, for example, the buffer capacity for jitter absorption may be sufficiently increased by increasing memory amount in the terminal. However, the memory is the one mainly determining the price of the terminal, and as to the price, 20 the cheaper is desirably the better. Also, if the buffer capacity for jitter absorption is too large, a time to access a specific frame resultantly takes longer, causing the user to feel irritated.

25 SUMMARY OF THE INVENTION

[0018] Therefore, an object of the present invention is to provide a streaming method for preventing streaming playback from being disturbed due to underflow and overflow of a buffer even if the buffer capacity in the terminal varies depending on device type, and even if the transmission capacity of the network fluctuates. Further, while preventing streaming playback from being disturbed, the streaming method can also reduce a time taken to access a specific frame.

[0019] The present invention has the following features to attain the object above.

[0020] A first aspect of the present invention is directed to a streaming method in which a server transmits stream data to a terminal over a network, and the terminal plays back the stream data while receiving the same, the method comprising:

15 a target value determination step of determining, by the terminal, a target value of the stream data to be stored in a buffer of the terminal in relation to a buffer capacity and a transmission capacity of the network,

20 a delay time determination step of arbitrarily determining, a delay time from when the terminal writes head data of the stream data to the buffer to when the terminal reads the data to start playback, by the terminal, in a range not exceeding a value obtained by dividing the buffer capacity by the transmission capacity;

25 a step of notifying, by the terminal, the determined

target value and the delay time to the server; and

a control step of controlling a transmission speed based on the notified target value and the delay time when the server transmits the stream data to the terminal over the network.

5 [0021] As described above, in the first aspect, the terminal itself determines a target value in relation to its own buffer capacity and the transmission capacity of the network. The terminal also determines a delay time within a value range not exceeding a value obtained by dividing the buffer capacity by the
10 transmission capacity. Based on the target value and the delay time thus determined by the terminal, the server accordingly controls the transmission speed. Therefore, even if the buffer capacity varies due to the device type, and even if the transmission capacity of the network fluctuates, the transmission
15 speed can be appropriately controlled according to the buffer capacity and the transmission capacity. As a result, streaming playback due to underflow and overflow of the buffer is successfully undisturbed. What is better, the delay time is determined separately from the target value, therefore the
20 streaming playback can be avoided, and at the same time, the waiting time to access a specific frame is reduced.

[0022] Here, the reason why the delay time is limited to a value equal to or smaller than the value obtained by dividing the buffer capacity by the transmission capacity is, if the delay time
25 exceeds the value, streaming playback is likely to be disturbed.

If not exceeding the value, the delay time may take any value. Note here that, to determine the value, there needs to consider a balance between the resistance to the fluctuation of the transmission capacity and a waiting time to access any specific
5 frame.

[0023] According to a second aspect, in the first aspect, in the control step, the server controls the transmission speed so that an amount of the stream data stored in the buffer of the terminal changes in the vicinity of the target
10 value without exceeding the target value.

[0024] As described above, in the second aspect, the storage changes in the vicinity of the target value without exceeding it. Therefore, the buffer hardly underflows and overflows.

[0025] According to a third aspect, in the second aspect,
15 in the control step, the server estimates and calculates the amount of the stream data stored in the buffer of the terminal based on the transmission speed, the delay time, and a speed of the terminal decoding the stream data.

[0026] As described above, in the third aspect, the server
20 estimates and calculates the storage, and based thereon, the transmission speed is controlled. Therefore, the storage can be changed in the vicinity of the target value without exceeding it.

[0027] Here, the terminal may notify the current storage to the server, and based on the information, the server may control
25 the transmission speed. If this is the case, however, it takes

time to transmit the information from the terminal to the server, and thus the server controls the transmission speed based on the previous storage. Therefore, the storage is not always be change in the vicinity of the target value without exceeding it.

5 [0028] According to a fourth aspect, in the first aspect, the streaming method further comprises:

a detection step of detecting, by the terminal, that the transmission capacity of the network exceeds a predetermined threshold value;

10 a target value change step of changing, by the terminal, the target value based on a result detected in the detection step; and

a step of notifying, by the terminal, a new target value after the change to the server, wherein

15 in the control step, when receiving the new target value after the change, the server controls the transmission speed so that the amount of the stream data stored in the buffer of the terminal changes in the vicinity of the new target value after the change without exceeding the new target value after the
20 change.

[0029] As described above, in the fourth aspect, when the transmission capacity exceeds the threshold value, the target value is changed by the terminal. The server follows the change of the target value by controlling the transmission speed to be
25 changed in the vicinity of the changed target value without

exceeding it.

- [0030] According to a fifth aspect, in the fourth aspect, in the detection step, when detecting the transmission capacity of the network as being fall short of a first threshold value, the terminal controls the target value to be increased in the target value change step, and
- in the control step, responding to the target value as being increased, the server controls the transmission speed to be increased.
- [0031] As described above, in the fifth aspect, when the transmission capacity exceeds the first threshold value, the target value is increased by the terminal. The server then follows the increase of the target value by increasing the transmission speed.
- [0032] According to a sixth aspect, in the fifth aspect, the first threshold value is approximately a median value of an achievable maximum transmission capacity and a transmission capacity with which a stream data transfer loss starts occurring.
- [0033] As described above, in the sixth aspect, when the transmission capacity starts decreasing, before any stream transfer loss starts occurring, the transmission speed is increased to increase the storage. In this manner, even if the transmission capacity is further decreased, streaming playback is successfully avoided.

[0034] According to a seventh aspect, in the fourth aspect, in the detection step, when detecting that the transmission capacity of the network as being fall short of a second threshold value which is smaller than the first threshold value, the terminal controls the target value to be decreased in the target value change step, and

in the control step, responding to the target value as being decreased, the server controls the transmission speed to be decreased.

10 [0035] As described above, in the seventh aspect, when the transmission capacity falls short of the second threshold value, the target value is decreased by the terminal. The server then follows the decrease of the target value by decreasing the transmission speed.

15 [0036] According to an eighth aspect, in the seventh aspect, the second threshold value is a value corresponding to the transmission capacity with which the stream data transfer loss starts occurring.

20 [0037] As described above, in the eighth aspect, when the transmission capacity starts decreasing to a greater degree, and when the stream transfer loss starts occurring, the transmission speed is then decreased. This is done not to disturb the processing of retransmitting the lost data.

[0038] Here, to decrease the transmission speed, the server needs to skip transmitting the frames with a frequency according

to the decrease. With the frame skip, the quality of the image and audio to be played back by the terminal resultingly deteriorates. To suppress this quality deterioration, in the following ninth aspect, selected for the frame to be skipped is
5 any frame which cannot be in time for its presentation time. In a tenth aspect below, selected for the frame to be skipped is any frame with lower priority, and any frame which cannot be in time for its presentation time although its priority is high.

[0039] According to a ninth aspect, in the eighth aspect,
10 when the terminal controls the target value to be decreased in the target value change step, in the control step, the server controls the transmission speed to be decreased by comparing a presentation time of every frame structuring the stream data to be transmitted with a current time, and skipping
15 transmitting any frame whose presentation time is older than the current time.

[0040] As described above, in the ninth aspect, any frame which cannot be in time for its presentation time is selectively skipped. In this manner, compared with a case where frame skip is performed
20 at random, the quality deterioration due to the decrease of the transmission speed can successfully suppressed.

[0041] According to a tenth aspect, in the eighth aspect,
when the terminal controls the target value to be decreased in the target value change step, in the control step,
25 the server

compares a priority level of every frame structuring
the stream data to be transmitted with a reference value,
skips transmitting every frame whose priority level
is lower than the reference value, and

5 for any frame whose priority level is higher than
the reference value, compares every presentation time with the
current time, and skips transmitting any frame whose presentation
time is older than the current time.

[0042] As described above, in the tenth aspect, any frame with
10 lower priority and any frame which cannot be in time for its
presentation time although its priority is high is selectively
skipped. In this manner, compared with a case where frame skip
is performed at random, the quality deterioration due to the
decrease of the transmission speed can successfully suppressed.

15 [0043] Here, such method in the tenth aspect as considering
the priority level together with the presentation time at the time
of frame selection is typically applied to video frames by MPEG.
In this case, when the transmission speed is decreased, the frames
of *P* and *B* are skipped as considered low in priority level.

20 However, the frames of *I* are considered high in priority level
and not skipped except for a case where those cannot be in time
for their presentation time. Therefore, the quality
deterioration due to the decrease of the transmission speed is
minimized in any played back image. Here, if this method is
25 applied to audio frames by MPEG, those are similar in priority

level, and thus considered in such case is only the presentation time.

[0044] An eleventh aspect is directed to a system including a server for transmitting stream data over a network, and a 5 terminal for playing back the stream data while receiving the same,

the terminal comprises:

target value determination means for determining a target value of stream data to be stored in a buffer of the terminal 10 in relation to a buffer capacity and a transmission capacity of the network;

delay time determination means for arbitrarily determining, in a range not exceeding a value obtained by dividing the buffer capacity by the transmission capacity, a delay time 15 from when the terminal writes head data of the stream data to the buffer to when the terminal reads the data to start playback; and

means for notifying the determined target value and the delay time to the server; and

the server comprises control means for controlling a 20 transmission speed based on the notified target value and the delay time when transmitting the stream data to the terminal over the network.

[0045] A twelfth aspect of the present invention is directed to a terminal working with a server for transmitting stream data 25 over a network, and playing back the stream data while receiving

the same, and

the server comprises control means for controlling a transmission speed based on a target value and a delay time when transmitting the stream data to the terminal over the network.

5 and

the terminal comprises:

target value determination means for determining the target value of the stream data to be stored in a buffer in relation to a buffer capacity of the terminal and a transmission 10 capacity of the network;

delay time determination means for arbitrarily determining, in a range not exceeding a value obtained by dividing the buffer capacity by the transmission capacity, the delay time from when the terminal writes head data of the stream data to the 15 buffer to when the terminal reads the data to start playback; and

means for notifying the determined target value and the delay time to the server.

[0046] A thirteenth aspect of the present invention is directed to a server for transmitting stream data over a network, 20 and working together with a terminal for playing back the stream data while receiving the same,

the terminal comprises:

target value determination means for determining a target value of the stream data to be stored in a buffer of the 25 terminal in relation to a buffer capacity and a transmission

capacity of the network;

delay time determination means for arbitrarily determining, in a range not exceeding a value obtained by dividing the buffer capacity by the transmission capacity, a delay time 5 from when the terminal writes head data of the stream data to the buffer to when the terminal reads the data to start playback; and means for notifying the determined target value and the delay time to the server; and

the server comprises control means for controlling a 10 transmission speed based on the notified target value and the delay time when the server transmits the stream data to the terminal over the network, wherein

the control means controls the transmission speed so that the amount of the stream data stored in the buffer of the 15 terminal changes in the vicinity of the target value without exceeding the target value.

[0047] A fourteenth aspect of the present invention is directed to a program describing such streaming method as the first aspect in the above.

20 [0048] A fifteenth aspect of the present invention is directed to a recording medium on which such program as the fourteenth aspect in the above is recorded.

[0049] These and other objects, features, aspects and advantages of the present invention will become more apparent from 25 the following detailed description of the present invention when

taken in conjunction with the accompanying drawings.

BRIEF DESCRIPTION OF THE DRAWINGS

DESCRIPTION OF THE PREFERRED EMBODIMENT

[0051] With reference to the accompanying drawings, an embodiment of the present invention is described. FIG. 1 is a block diagram showing an example of the structure of a server-client system wherein a streaming method according to the present embodiment is carried out. In FIG. 1, the present system includes a server 101, and a terminal 101 operating as a client for the server 101. On the server 101 side, data such as video and audio is stored. This data has been encoded and compressed by MPEG. The server 101 responds to a request from the terminal 102, and generates a stream by assembling the stored data into packets. Then, the server 101 transmits thus generated stream to the terminal 102 over a network 103. The terminal 102 receives and decodes the stream, and outputs resulting video and audio for display.

[0052] FIG. 2 is a block diagram showing the structure of the server 101 of FIG. 1. In FIG. 2, the server 101 includes a storage device 411, a transmission/reception module 402, a generation module 405, RAM 404, a CPU 412, and ROM 413. The storage device 411 stores data such as video and audio. The data stored in the storage device 411 is provided to the generation module 405. The generation module 405 includes a reading buffer 407, a packet assembling circuit 406, and a packet assembling buffer 408, and generates a stream by assembling any received data into packets.

[0053] The transmission/reception module 402 includes a network controller 410, and a transmission buffer 409. The transmission/reception module 402 transmits the stream generated by the generation module 405 to the terminal 102 over the network 103, and also receives any information coming from the terminal 102 over the network 102.

[0054] The information from the terminal 102 received by the transmission/reception module 402 is written into the RAM 404. The ROM 413 stores a server control program, and the CPU 412 executes the program while referring to the information stored in the RAM 404. Thereby, the CPU 412 controls the transmission/reception module 402 and the generation module 405. Here, the program is not necessarily stored in the ROM 413 but may be stored in a recording medium excluding the ROM, for example, in a hard disk and a CD-ROM.

[0055] FIG. 3 is a block diagram showing the structure of the terminal 102 of FIG. 1. In FIG. 3, the terminal 102 includes a transmission/reception module 507, a playback module 510, a display device 511, ROM 502, and a CPU 503. The transmission/reception module 507 includes a network controller 506, and a reception buffer 505, and receives any stream coming from the server 101 over the network 103. Also, the transmission/reception module 507 transmits any information from the CPU 503 to the server 101 over the network 103.

[0056] The stream received by the transmission/reception

module 507 is inputted to the playback module 510. The playback module 510 includes a decoder buffer 508, and a decoder 509, and decodes and plays back the inputted stream. The data played back by the playback module 510 is then provided to a display device 511. The display device 511 then converts the data into a video for display.

[0057] The ROM 502 stores a terminal control program, and the CPU 503 executes the program to control the transmission/reception module 507, the playback module 510, and the display device 511.

[0058] Described next is the operation of the system in such structure. FIG. 4 is a sequence diagram for illustrating the comprehensive operation of the system of FIG. 1. FIG. 4 shows a transmission/reception layer and a control layer on the server 101 side, another transmission/reception layer and control layer on the terminal 102 side, and commands and streams exchanged between those layers arranged in time sequence.

[0059] Described first is the comprehensive operation of the present system with reference to FIG. 4. In FIG. 4, a command "SETUP" is transmitted from the terminal 102 to the server 101. In response to the command "SETUP", the server 101 performs initialization, and once completed, transmits an "OK" to the terminal 102.

[0060] In response to the "OK" from the server 101, the terminal 102 then transmits a command "PLAY" to the server 101. In response,

the server starts making preparation for transmission, and once completed, transmits an "OK" to the terminal 102.

[0061] In response to the "OK" from the server 101, the terminal 102 transits to be a state waiting for data streams. Then, the 5 server 101 first transmits the "OK", and then starts transmitting the data streams.

[0062] Thereafter, the terminal 102 transmits a command "TEARDOWN" to the server 101, and the server 101 responsively terminates transmitting the data streams. Once transmission is 10 terminated, the server 101 transmits an "OK" to the terminal 102.

In response to the "OK" from the server 101, the terminal 102 exits from the waiting state for the data streams.

[0063] This is the brief description of the comprehensive operation of the present system. As far as the description above 15 is concerned, the present system operates the same as the conventional system. The differences therebetween are the following two respects (1) and (2).

(1) The command "SETUP" from the terminal 102 to the server 101 are attached with parameters "S_target" and "T_delay".
20 When transmitting the data streams, the server 101 controls the transmission speed based on these parameters.

[0064] In the above (1), the parameter "S_target" is a target value for the data amount to be stored in the buffer by the terminal 102, and determined based on the entire capacity ("S_max") of the 25 buffer included in the terminal 102 (in the example of FIG. 3,

the reception buffer 505 and the decoder buffer 508) and the transmission capacity of the network 103. Therefore, the parameter "S_target" generally varies in value depending on the type of the terminal 102.

5 [0065] The parameter "T_delay" is a time taken for the terminal 102 to write the head data to the buffer, read the data, and start decoding the data (that is, a delay time to access a specific frame), and arbitrarily determined within a value range not exceeding the value obtained by dividing the parameter "S_target" by the 10 transmission speed (will be described later). Here, although such condition is composed as "not exceeding the value obtained by dividing the parameter "S_target" by the transmission speed", the terminal 102 can determine the parameter "T_delay" separately from the parameter "S_target".

15 [0066] Here, the "transmission speed" indicates the amount of information to be transmitted within a unit time. For example, in the case that the number of packets to be transmitted in the unit time is determined in advance, the amount of data to be provided to one packet can be increased/decreased to control the 20 transmission speed. If the amount of data in one packet is determined in advance, the temporal interval between any two packets may be shortened/lengthened to control the transmission speed. Alternatively, both of those may be simultaneously carried out to control the transmission speed, that is, the amount 25 of data provided to one packet is increased/decreased, and the

temporal interval between any two packets is shortened/lengthened.

In the present embodiment, the amount of data in one packet is increased/decreased to control the transmission speed.

5 [0067] (2) The terminal 102 can change the parameter "S_target" as required during when distributing the data streams.

If this is the case, the parameter "S_target" after the change is transmitted from the terminal 102 to the server 101, and the server 101 accordingly controls the transmission speed based on the newly received parameter "S_target".

10 [0068] In the above (2), the parameter "S_target" is changed according to the fluctuation of the transmission capacity of the network 103. To be specific, assuming that the terminal 102 is a mobile phone, the field intensity (e.g., four intensity levels of "high, medium, low, out of area") can be detected. Thus, any 15 change observed in the field intensity is regarded as "the change of transmission capacity of the network 103", and accordingly the parameter "S_target" is changed. For example, if the field intensity is changed from "high" to "medium", the terminal 102 changes the parameter "S_target" to a larger value, and if changed 20 from "medium" to "low", the parameter "S_target" is changed to a smaller value.

These are the main two points considered as being the operational differences between the present and conventional systems.

25 [0069] Described next is the specific example of the

comprehensive operation of the present system in detail. In FIG.
4, prior to starting streaming playback on the terminal 102 side,
the CPU 503 extracts from the ROM 502 a group of parameters unique
to the terminal by following the terminal control program. In
5 the group of parameters, the parameter S_{max} indicating the total
capacity of the reception buffer 505 and the decoder buffer 508
(i.e., the maximum amount of data actually storable by the
terminal 102). Here, presumably, the CPU 503 has been informed
in advance of an encoding and compressing rate V_r of any data stream
10 and a frame occurrence cycle T_{frm} of video and audio through the
procedure for previously obtaining streaming playback auxiliary
data, and the like. Also, presumably, the CPU 503 has detected
the transmission capacity of the network 103 via the network
interface, including the intensity of radio wave received by the
15 mobile phone, and communication speed (as for a PHS, information
telling which of 64 Kbps connection and 32Kbps connection), for
example.

- [0070] Based on the parameter S_{max} , rate V_r , cycle T_{frm} , and
the transmission capacity of the network 103 (e.g., effective
20 transfer rate = *networkRate*), the CPU 503 then determines the
parameters S_{target} being a target value for the data amount to
be stored in the buffer by the terminal 102, and a prebuffering
time T_{delay} (i.e., delay time to access any specific frame) taken
to start streaming playback.
- 25 [0071] Here, the parameter S_{target} is, in the essential sense,

a reference value for streaming playback to be started. With the parameter S_target, streaming playback can be continuously and normally performed under the condition that the buffer occupancy of the terminal changes in the vicinity of the parameter S_target.

- 5 As described above, if the value of the parameter T_delay is large, the time to access any specific frame takes longer. On the other hand, the resistance to the transfer jitter is improved. The issue here is, if the delay time takes too long, it is considered inappropriate as service specifications. Accordingly, to
10 determine the parameter T_delay, the resistance to the transfer jitter and the waiting time to access any specific frame need to be well balanced.

[0072] Here, instead of the parameter T_delay, or together therewith, another parameter S_delay may be determined. Here, the parameter S_delay indicates the amount of data (Byte), and once the buffer in the terminal 102 reaches the amount, decoding is preformed. In the case that the terminal 102 determines only the parameter S_delay and notifies that to the server 101, the parameter S_delay can be converted into the parameter T_delay on the server 101 side by applying such equation as $T_{delay} = S_{delay}/networkRate$. Here, the value of the parameter S_delay may indicate a filling rate $rS(\%)$ with respect to the total buffer occupancy S_max. If this is the case, the equation for conversion is $S_{delay} = S_{max} * rS/100$.

- 25 [0073] When those parameters S_target and T_delay (and /or

S_delay) are ready, as shown in FIG. 4, the terminal 102 issues a SETUP command prompting the server 101 to prepare for data stream distribution. The SETUP command includes, as arguments, the parameters S_target and T_delay (and/or S_delay). Once received 5 the SETUP command, the server 101 stores those arguments in the RAM 404, and goes for initialization for data stream distribution. Specifically, the CPU 412 of the server 101 first extracts those arguments from the memory 404. Then, for example, a source file 10 of the data stream is read from the storage device 411 and written to the buffer 407, and a parameter for the packet assembling circuit 406 wherein thus read data is assembled into packets is set. Herein, the packet assembling circuit 406 is not necessarily 15 dedicated hardware, and may be a program (software algorithm) for causing the CPU 412 in the server 101 (for example, realized by a workstation) to execute the packet assembly processing in the similar manner.

[0074] Two values of the above-described parameters S_target and T_delay (and/or S_delay) are provided to the packet assembling circuit 406. In the packet assembling circuit 406, an optimal 20 rate control parameter is calculated by utilizing those values, and as a result, the packets are assembled and sent out with a rate suitable for distributing the data streams to the terminal 102. Once preparation is normally done for sending out the packet to the network 103, as shown in FIG. 4, the "OK" is returned from 25 the transmission/reception layer to the control layer, and then

in response to the SETUP command, another "OK" is returned to the terminal 102. In this manner, the system gets ready for distributing the data streams.

[0075] Then, the terminal 102 issues a PLAY command to prompt the server 101 to start distributing the data streams. In response to the PLAY command, the server 101 accordingly starts distributing the data streams. The terminal 102 receives and stores the data streams. Then, after a lapse of the above-mentioned prebuffering time (T_{delay}) since the terminal 102 started storing the data streams, the data streams are decoded and played back. At this time, needless to say, the data streams are distributed based on a rate control parameter which has been appropriately set at SETUP.

[0076] At the end of streaming playback, the terminal 102 issues a TEARDOWN command to the server 101. In response to the TEARDOWN command, the server 101 goes through processing to end data stream distribution, and ends the entire procedure. This is the end of the description of the specific operation of the present system.

[0077] Described below is the operation of the terminal 102 in detail. The terminal 102 is presumably a mobile phone connectable to the Internet, and is capable of detecting the field intensity (intensity of radio wave to be received thereby). FIG. 5 is a flowchart showing the operation of the terminal 102 of FIG.

1. In FIG. 5, the terminal 102 first determines values of the

two parameters S_target and T_delay (step S101).

[0078] Here, the processing carried out in step S101 is described in detail. FIG. 6 is a diagram showing the storage contents of the ROM 502 of FIG. 3. As shown in FIG. 3, the ROM

5 502 stores the terminal control program, a table 601 showing the correspondence between the field intensity and the parameter S_target, and the value of the parameter T_delay. Here, for the value of the parameter S_target, three values of S_target1 corresponding to the field intensity "high", S_target2 corresponding to the field intensity "medium", and S_target3 corresponding to the field intensity "low/out of area" are stored.

As to the parameter T_delay, only one value is stored.

[0079] Those three values of S_target1 to S_target3 are so determined as to satisfy the following relationship:

15 $S_{target3} < S_{target1} < S_{target2} \leq S_{max}$

On the other hand, the value T_delay is so determined as not to exceed the value obtained by dividing the value S_max by the effective transmission capacity of the network 103.

[0080] As an example, when the value S_max is 512(KB),

20 S_target1 = 256(KB), S_target2 = 384 (KB), and S_target3 = 128(KB) are thus determined, for example. Also, assuming that the effective transmission capacity of the network 103 is 384(Kbps), that is, 48(KB/sec), the value T_delay may be so determined as not to exceed $512 \div 48 \approx 10.7$, and arbitrarily determined such 25 as 4 seconds and 3 seconds, for example.

[0081] In step S101, read from the ROM 502 are the parameter S_target1 as an initial value and the value T_delay.

[0082] Note herein that the values of S_target1 to S_target3, and T_delay are calculated in advance and stored in the ROM 502, 5 and the CPU 503 reads from the ROM 502 any value in need. Alternatively, the ROM 502 may previously store a program for calculating the buffer capacity in total, the effective transmission capacity of the network 103, and the values of the parameters S_target and T_delay. If this is the case, the CPU 10 503 may read the ROM 502 for the capacity, speed, and the program as required, and calculate the values of S_target and T_delay. In this example, although only one value is stored for the parameter T_delay, this is not restrictive, and several values may be stored in advance for selection thereamong. This is the 15 processing carried out in step S101.

[0083] Refer back to FIG. 5. The terminal 102 attaches the parameters S_target and T_delay determined in step S101 to the SETUP command, and transmits it to the server 101 (step S102). In response, the server 101 transmits the data streams to the 20 terminal 102. When the data streams are transmitted, the server 101 controls the transmission speed based on the parameters S_target and T_delay notified by the terminal (the operation on the server side will be described later).

[0084] Then, the terminal 102 receives the data streams coming 25 from the server 101, and starts operating for buffer writing (step

S103). To be specific, as shown in FIG. 3, the data streams coming over the network 103 are first written to the reception buffer 505 via the network controller 506. After a lapse of time and the reception buffer 505 is filled, the data streams in the 5 reception buffer 505 are read in order from the head, and written into the decoder buffer 508.

[0085] Next, the terminal 102 determines whether the time has passed for T_delay since buffering has started (step S104), and if determined No, waits until the determination becomes Yes. Once 10 the determination in step S104 becomes Yes, the terminal 102 reads the data streams from the buffer, and starts operating for decoding and playback (step S105). To be more specific, in FIG. 3, the CPU 503 is measuring the time since buffering has started, and once the measurement coincides with the value T_delay in the 15 ROM 502, the playback module is instantaneously instructed to start processing of reading the data streams in the decode buffer 508 in order from the head, and inputting those to the decoder 509.

[0086] Then, the terminal 102 determines whether the 20 transmission capacity of the network 103 changes and exceeds its threshold value (step S106). Specifically, this determination is made as follows. For example, a host computer (not shown) managing the network 103 is so set as to distribute information about the transmission capacity of the network 103 to the terminal 25 102 over the network 103 whenever necessary. Based on the

information provided by the host computer, the terminal 102 then determines whether there is any change in the transmission capacity.

[0087] In such case, specifically, as shown in FIG. 3, the information about the transmission capacity is sent out to the CPU 503 via the transmission/reception module 507. The ROM 502 previously stores the threshold value, and by comparing the information, the retaining previous information, and the threshold value in the ROM 502 with one another, the CPU 503 can determine whether the transmission capacity has changed and exceeded the threshold value.

[0088] As another example, if the host computer managing the network 103 is not capable of distributing the information about the transmission capacity to the terminal 102, the terminal 102 can make the determination as follows. That is, in the case that the terminal 102 is a mobile phone, as shown in FIGS. 7A and 7B (will be described later), the terminal 102 is capable of detecting the field intensity therearound, and displays the result as "high", "medium", "low", or "out of area". By regarding the change of field intensity as the change of transmission capacity of the network 103, the terminal 102 can perform such detection easily.

[0089] If the determination in step S106 is Yes, the terminal 102 determines a new S_target (step S107), and transmits it to the server 101 (step S108). On the other hand, if the

determination in step S106 is No, the procedure skips steps S107 and S108, and goes to step S109 (will be described later).

[0090] Described now is the processing carried out in steps S106 and S107 in detail. In the below, described is an exemplary case where the terminal 102 is a mobile phone, and the value S_target is changed according to the change of field intensity.

FIG. 7A is a schematic diagram showing a field intensity distribution in a certain area, and FIG. 7B is also a schematic diagram showing the change of transmission capacity observed when the terminal moves. Here, the field intensity distribution shown in FIG. 7A covers the area including three relay stations B1 to B3. In FIG. 7A, three groups of concentric circles having the relay stations B1 to B3 each positioned at the center are coverage contours, which are derived by connecting points equal in field intensity.

[0091] By taking one group of concentric circles having the relay station B3 positioned at the center as an example, in a concentric circle 703 closest to the relay station B3, the field intensity is "high", and the field intensity in an area between this concentric circle 703 and another concentric circle 704 is "medium". Also, the field intensity in an area between the concentric circles 704 and 705 is "low", and an area outside of the concentric circle 705 is "out of area". Note that those groups of concentric circles partially overlap with one another, and the area being "out of area" in field intensity is quite small.

- [0092] Assuming that the terminal 102 is now moving from the vicinity of the relay station B_1 to the vicinity of the relay station B_2 along the path denoted by an arrow 702. FIG. 7B shows the field intensity along the arrow 702 of FIG. 7A. The field intensity here can be regarded as the transmission capacity of the network 103. As shown in FIG. 7B, when the terminal 102 is located in the vicinity of the relay station B_1 , the field intensity is "high", and as the terminal 102 moves away from the relay station B_1 , the field intensity starts changing to "medium", "low", and then "out of area". Immediately after the field intensity of the terminal 102 shows "out of area" of the relay station B_1 , the terminal 102 is again "in area" of the relay station B_2 , and the field intensity starts gradually changing to "low", "medium", and then "high".
- [0093] Immediately after the field intensity changes from "high" to "medium", the terminal 102 moving as such determines that the transmission capacity of the network 103 has changed and exceeded a threshold value A , and thus determines a new S_{target} , and immediately after a change from "medium" to "low", the transmission capacity is determined as changed and exceeded a threshold value B , and a new S_{target} is determined. On the other hand, immediately after the field intensity changes from "low" to "medium", the terminal 102 determines that the transmission capacity of the network 103 has changed and exceeded the threshold value B , and thus determines a new S_{target} , and immediately after

a change from "medium" to "high", the transmission capacity is determined as changed and exceeded the threshold value A , and a new S_{target} is determined.

[0094] Note that, generally, the threshold value A is approximately a median value of the maximum transmission capacity achievable by the network 103 and the transmission capacity with which a transfer loss in streaming starts to occur. The threshold value B is a value corresponding to the transmission capacity with which the transfer loss in streaming starts occur.

[0095] The new S_{target} is determined as follows by referring to the table 601 (see FIG. 6) in the ROM 502. FIG. 8 is a flowchart showing the details of step S107 of FIG. 5. In FIG. 8, the terminal 102 first determines whether the field intensity after a change shows "high" or not (step S201), and if determined Yes, a new S_{target} is set to the value $S_{target1}$ (step S202). If the determination in step S201 is No, the procedure skips step S202, and goes to step S203.

[0096] Then, the terminal 102 determines whether the field intensity after the change is "medium" (step S203), and if determined Yes, the new S_{target} is set to the value $S_{target2}$ (step S204). If the determination in step S203 is No, the procedure skips step S204, and goes to step S205.

[0097] The terminal 102 then determines whether the field intensity after the change is "low/out of area" (step S205), and if determined Yes, the new S_{target} is set to the value $S_{target3}$.

(step S206). Then, the procedure returns to the flow of FIG. 5.

If the determination in step S205 is No, the procedure skips step S206, and returns to the flow of FIG. 5.

[0098] Therefore, if the terminal 102 moves along the arrow 5 702 of FIG. 7A, according to the change of field intensity, the terminal 102 changes the value of the parameter S_target as S_target1 → S_target2 → S_target3 → S_target2 → S_target1. As a specific example, the change will be 256(KB) → 384(KB) → 128(KB) → 384(KB) → 128(KB). This is the end of the description 10 about steps S106 and S107 in detail.

[0099] Refer back to FIG. 5. In step S108, when the terminal 102 transmits the new S_target to the server 101, the server 101 responsively changes the value of the parameter S_target to the value newly notified by the terminal 102, and continues 15 controlling the transmission speed.

[0100] The terminal 102 then determines whether now is the time to end streaming playback (step S109), and if determined Yes, transmits the command TEARDOWN to the server 101, and stops receiving and buffering the data streams (step S110). Then, the 20 playback processing is stopped (step S111). On the other hand, if determined as continuing streaming playback, the procedure returns to step S106, and repeats the same processing as above. This is the operation of the terminal 102.

[0101] Described next is the operation of the server 101 in 25 detail. Here, for the sake of simplicity, the server 101 performs

encoding with an encoding and compressing algorithm for occurring frames with a fixed cycle T_{frm} such as MPEG-1 video (ISO/IEC 11172-2), MPEG-2 video (ISO/IEC 13818-2), and MPEG-2 AAC audio (ISO/IEC 13818-7), for example. Also, the server 101 performs 5 packet assembly on the encoded data with a fixed cycle T_s . Here, this packet assembly is performed on a frame basis.

[0102] With reference to FIGS. 9 to 11, described first is the control on the transmission speed in streaming performed by the server 101. FIGS. 9 to 11 are diagrams showing the change of 10 amount of data (buffer occupancy) stored in the buffer in the terminal 102 by the control on the transmission speed in streaming performed by the server 101. The server 101 controls the transmission speed in streaming so that the buffer occupancy in the terminal 102 receiving data changes as shown in FIGS. 9 to 15 11.

[0103] FIG. 9 shows how the buffer occupancy gets nearer to the value S_{target} . FIG. 10 shows how the buffer occupancy gets nearer to the value $S_{target2}$ in a case where the buffer occupancy is changing in the vicinity of S_{target} , and the value of S_{target} 20 is changed to a larger value ($S_{target2}$). FIG. 11 shows how the buffer occupancy gets nearer to the value $S_{target3}$ in a case where the buffer occupancy is changing in the vicinity of S_{target} , and the value of S_{target} is changed to a smaller value ($S_{target3}$).

[0104] As applicable to all of FIGS. 9 to 11, the value "S_max" 25 indicates the total capacity of the buffer in the terminal 102,

and "Sum" denotes the buffer occupancy. " $\delta(0, 1, 2, \dots)$ " indicates the amount of data to be transmitted by the server 101 in a unit time T_s , that is, the amount of data included in one packet. Here, the unit time T_s denotes a cycle for the server 5 101 to perform packet transmission, and is a fixed value. " $L(0, 1, 2, \dots)$ " denotes the amount of data for one frame.

[0105] Once received the value of the parameter T_{delay} from the terminal 102, the server 101 controls the transmission speed in streaming based on the value. This speed control is performed 10 by changing the amount of data included in one packet.

[0106] As shown in FIG. 9, the amount of data in the packet ($i=0$) first transmitted by the server 101 is δ_0 . At a time $t=0$, the buffer occupancy Sum is δ_0 . After the unit time T_s , the next packet ($i=1$) including data of δ_1 comes. At a time 15 $t=T_s$, the Sum thus becomes $\{\delta_0 + \delta_1\}$. Thereafter, every time the unit time T_s passes, the packets continuously come, and the Sum is increased by $\delta_2, \delta_3, \dots$, and so on.

[0107] Here, before the third packet ($i=2$) comes, that is, at a time $t=T_{\text{delay}}$, processing is started for reading data from the 20 buffer and decoding it. Here, decoding is performed on a frame basis, and thus after the time $t=T_{\text{delay}}$, the Sum is decreased by $L_0, L_1, L_2 \dots$ every time the fixed cycle T_{frm} passes.

[0108] That is, after the time $t=0$, the buffer occupancy Sum is gradually increased by $\delta_0, \delta_1 \dots$ every time the cycle 25 T_s passes. Then, after the time $t=T_{\text{delay}}$, the sum is decreased

by L₀, L₁, L₂... every time the cycle *Tfrm* passes. Accordingly, in the time period immediately before the buffer occupancy *Sum* reaching the target value S_target, the amount of data included in one packet may be set larger than usual, more generally, the 5 transmission speed is increased so that the speed for buffer writing is faster than the speed for buffer reading. After the time period, the amount of data in one packet is put back to normal so as to balance the speeds of buffer writing and reading. In this manner, the buffer occupancy *Sum* can be changed in the 10 vicinity of the target value S_target.

[0109] With such control of transmission speed, as shown in FIGS. 10 and 11, even if the target value S_target is changed to a new target value such as S_target2 and S_target3, the buffer occupancy *Sum* can be changed in the vicinity of the new target 15 value such as S_target2 and S_target3.

[0110] That is, in FIG. 10, in a case where the buffer occupancy *Sum* is changing in the vicinity of the target value S_target, if the value of S_target is changed to a larger value (S_target2), the server 101 increases the amount of data to be included in the 20 packets (*i*=3, 4) so that the speed of buffer writing becomes faster than the speed of buffer reading. After the buffer occupancy *Sum* reached the new target value S_target2, the amount of data to be provided to one packet is put back to normal, and the writing speed and reading speed are to be balanced.

25 [0111] In FIG. 11, in a case where the buffer occupancy *Sum*

is changing in the vicinity of the target value S_{target} , if the value of S_{target} is changed to a smaller value ($S_{target3}$), the server 101 decreases the amount of data to be included the packets ($i=3, 4$) so that the speed of buffer writing becomes slower than the speed of buffer reading. After the buffer occupancy Sum reached the new target value $S_{target3}$, the amount of data to be provided to one packet is put back to normal, and the writing speed and reading speed are to be balanced.

[0112] Described next is the transmission speed control performed by the server 101 more in detail. FIG. 12 is a flowchart showing an exemplary algorithm for the transmission speed control by the server 101. In FIG. 12, first of all, the terminal 102 detects its own buffer occupancy (Sum), and the server 101 receives the buffer occupancy Sum from the terminal 102 (step S301). Then, the server 101 determines whether the buffer occupancy Sum notified in step S301 is changing in the vicinity of the target value S_{target} specified by the terminal 102 (step S302). If the determination is Yes, the current transmission speed is maintained.

[0113] If the determination in step S302 is No, the server 101 then determines whether the buffer occupancy Sum notified in step S301 is larger than the target value S_{target} (step S303). If the determination is No, the transmission speed is increased (step S304), and the procedure then goes to step S306. On the other hand, if the determination in step S303 is Yes, the transmission

speed is decreased (step S305), and then the procedure goes to step S306.

[0114] In step S306, it is determined whether the speed control operation is continuously performed, and if determined Yes, the 5 procedure returns to step S301, and the same operation as above is repeated. On the other hand, if the determination is No, this is the end of operation. This is the example of the transmission speed control performed by the server 101.

[0115] Note that, in the example of FIG. 12, the terminal 102 10 itself detects its own buffer occupancy and notifies it to the server 101. In this case, however, detected by the terminal 102 is the buffer occupancy at that time. Further, it takes time to transmit information from the server 102 to the server 101, and thus the server 101 performs the transmission speed control based 15 on the buffer occupancy in the past for the delayed time. Therefore, it is actually difficult to make the buffer occupancy change in the vicinity of the value S_{target} .

[0116] In another example to be described below (see FIGS. 13 and 14), the server 101 performs the transmission speed control 20 based on the buffer occupancy at a certain point of time in the future. In this manner, the buffer occupancy can be changed in the vicinity of the value S_{target} . In this case, instead of being notified by the terminal 102 of the buffer occupancy Sum , the server 101 estimates and calculates the buffer occupancy Sum on 25 the terminal 102 side at a certain point in time in the future.

This estimation and calculation are carried out as follows.

[0117] That is, in FIG. 2, the ROM 413 previously stores the packet transmission cycle T_s (fixed value) and the decoding cycle T_{frm} (fixed value). At the time of packet assembly, the CPU 412 5 stores the amount of data in one packet (e.g., delta0, delta1, and the like) in the RAM 404. Also, at the time of data stream transmission, the amount of data in each frame (e.g., L0, L1, and the like) is stored in the RAM 404.

[0118] The RAM 404 includes the value T_{delay} previously 10 notified by the terminal 102. By referring to the cycles T_s and T_{frm} in the ROM 413 and the values delta(0, 1, 2, ...) and T_{delay} in the RAM 404, and performing the predetermined computation, the CPU 412 can calculate the buffer occupancy at a certain time in 15 the future. With such computation processing, the server 101 can estimate the change of buffer occupancy Sum on the terminal 102 side (see FIGS. 9 to 11).

[0119] With reference to FIGS. 9, 13, 14, and 15, described now is a specific example of the transmission speed control carried out by the server 101 by estimating and calculating the 20 buffer occupancy Sum on the terminal 102 side.

[0120] In FIG. 9, the value S_{max} indicates the maximum value of the effective storage of the buffer in the terminal 102, and is simply referred to as a "total buffer capacity". The value S_{target} indicates a target value for the data amount to be stored 25 in the buffer in the terminal 102 in current streaming, and the

value T_{delay} is a setting value for the delay time taken to access a specific frame. What these parameters indicate are already described in the foregoing. In the below, assuming that the terminal 102 has already notified both values of S_{target} and

5 T_{delay} .

[0121] In the present embodiment, for easy understanding, shown is an example that packet assembly and distribution is carried out on the fixed time cycle T_s basis (packet distribution at a time corresponding to $i=n$, where n is a positive integer).
10 Here, when packet distribution is performed at the time corresponding to $i=n$ ($t=i*T_s$), the buffer capacity Sum of the reception buffer 505 and the decoder buffer 508 in the terminal 102 both show instantaneous increase in data amount equivalent to the number of frames. This is because, as shown in (A) of FIG.
15 15, packet assembly is performed in a pattern of inserting a plurality of frames to one packet, and the resulting packet is distributed to the terminal 102. Actually, although packet distribution takes time due to transfer, and thus the buffer occupancy does not instantaneously increase as shown in the
20 drawing (the slope indicates the $networkRate$), it is considered a simplified model. The staircase decrease in buffer occupancy after the time $t=T_{delay}$ means that, at that time, streaming playback has started in the terminal 102. That is, for every frame presentation cycle T_{frm} , data processing is carried out by the
25 decoder 509 on the frame length $L=L[k]$ basis (where k is a positive

integer).

[0122] FIGS. 13 and 14 are flowcharts showing an exemplary algorithm for transmission control performed by the server 101 to realize the change of buffer occupancy shown in FIG. 9.

5 Specifically, FIG. 13 shows the entire algorithm, and FIG. 14 shows an exemplary function *mkPacket* in step S404 in FIG. 13. The ROM 413 (see FIG. 2) stores a program having such algorithm written thereon, and by following this program, the CPU 412 performs various computations and controls, realizing the change of buffer

10 occupancy shown in FIG. 9. Here, for the sake of simplification, the packet distribution is presumed not to be stopped during streaming. In the below, description is made step by step.

[0123] In FIG. 9, the server 101 receives and stores the values of S_target and T_delay transmitted from the terminal 102 (step

15 S401). To be specific, in FIG. 2, the values of S_target and T_delay transmitted over the network 103 from the terminal 102 are written into the RAM 404 via the network controller 410.

[0124] Herein, the terminal 102 determines the values of S_target and T_delay, and transmits the result to the server 101.

20 This is not restrictive, and the server 101 may store those values in advance, or store information about the device type of the terminal 102 (e.g., the total buffer capacity), and calculate those parameter values based on the information.

[0125] Then, each variable is initialized (steps S402, S403).

25 The meaning of each variable will be described later with

reference to FIG. 14. After the initialization is completed, the processing after step S404, that is, packet assembly with the function *mkPacket* and packet transmission to the network 103 is started. In this example, the assembled packets are distributed
5 to the terminal 102 in the fixed cycle *Ts*. Thus, the server 101 performs timing adjustment in step S405, and then packet transmission in step S406. After the processing, the CPU 412 updates an execution counter *i* of the function *mkPacket*, and the procedure returns to step S404 to enter the loop. After stream
10 data reading and packet assembly being completed, the CPU 412 exits from the function *mkPacket*, and the procedure returns to step S404 with a result of FALSE. At this time, the CPU 412 regards the distribution as being completed, and ends the algorithm. This is the description about the algorithm for transmission control.
15 [0126] As to the detailed algorithm of the function *mkPacket* shown in FIG. 404, described first is about each variable. The variable *Sum* indicates the total amount of data stored in the reception buffer 505 and the decoder buffer 508 in the terminal 102, *L* denotes the data amount in a frame, *delta* denotes the total
20 data amount assembled to packets after the function *mkPacket* is currently called, *in* denotes a counter indicating the number of frames of a stream source read from the storage device 411, *out* denotes a counter indicating the number of frames decoded by the decoder 509 in the terminal 102, *dts* is a time for the frame to
25 be decoded in the decoder 509, and *grid* is an upper limit value

of *dts* advanced during when one loop of the previous function *mkPacket* is processed.

[0127] In FIG. 14, the function *mkPacket* mainly includes a packet generation algorithm A1 and a decoding calculation 5 algorithm A2. As to the packet generation algorithm A1, in the first step (S501), the CPU 412 clears *delta*. In the following step S502, the CPU 412 determines whether the frame of $L=L[\text{in}]$ which is already read is to be used for the current packet assembly. The determination is made based on (a) the value obtained by adding 10 the buffer occupancy *Sum* and the value *L* do not exceed the value *S_target*, and (b) the value obtained by adding the data amount *delta* subjected to packet assembly by the current function call (the current amount of date included in one packet) and the value *L* do not exceed an upper limit *deltaMax*, which is the upper limit 15 for the data amount includable in one packet.

[0128] Here, *deltaMax* is a value satisfying an inequality in (A) of FIG. 15,

$$(\text{deltaMax} + \text{hdr}) / Ts < \text{NetworkRate}$$

and the maximum value of the data amount distributable to the 20 terminal in the cycle *Ts*. *Deltamax* can be calculated from the effective transfer rate (transmission capacity) of the network 103. When determined True in step S502, the procedure goes to step S503, and the CPU 412 performs packet assembly on the frame of $L=L[\text{in}]$. In the following step S504, after the packet assembly, 25 the CPU 412 then updates the values of *Sum* and *delta*. In step

S505, the CPU 412 then reads data on the next frame from the reading buffer 407, and reads the frame length L from the RAM 404. Then, the CPU 412 determines whether L is larger than 0.

[0129] When the determination in step S505 is No, that is, $L=0$, the CPU 412 regards every data has been completely read (detect End of File), and exits from the function. The procedure then returns to step S404 in the main flow (FIG. 13) with the result of FALSE. On the other hand, if the determination is Yes, that is, $L>0$, the procedure goes to the next step S506, and the CPU 412 includes the $L[in]$ in the sequence *leng*, that is, causes the RAM 404 to store it. This is due to using the decoding calculation algorithm A2, which will be later described. Then, the procedure goes to step S507, and the CPU 412 updates the frame number read counter *in*. The procedure then returns to step S502 to enter the loop.

[0130] By repeating packet assembly in the above loop, the values of *Sum* and *delta* become larger. In step S502, if the value *Sum* or *delta* is determined as being sufficiently large, the procedure exits from the loop, and enters the decoding calculation algorithm A2.

[0131] In the decoding calculation algorithm A2, in the first step S508, it is determined whether the value $i*T_s$ is equal to or larger than the value *grid*. This step S508 is through for determining whether now is the time for the terminal 102 to start decoding. Specifically, as the value *grid* is first set to the

value T_{delay} , the function calling counter i shows the small number and the value $t=i*T_s$ is smaller than the value $grid$, it is determined that decoding is not yet started in the terminal 102. In FIG. 9, the time corresponding to $i=0$ and $i=1$ correspond 5 thereto.

[0132] If the determination in step S508 is No, the CPU 412 exits from the function without subtraction processing on the frame data by decoding. On the other hand, if i becomes sufficiently large and the packet assembly time $t=1*T_s$ becomes 10 equal or larger than the value $grid$, the CPU 412 regards decoding in the terminal 102 has already started, and goes through the subtraction processing on the frame data. In FIG. 9, the time corresponding to i being 2 or larger corresponds thereto. In the loop between steps S509 to S512, the amount of frame data $leng[out]$ 15 subjected to decoding processing within the time between the current grid time and the next grid time ($=grid + T_s$) is subtracted from the buffer occupancy Sum . Also, the decoded frame number out is counted up.

[0133] In step S511 in the above loop, dst is added by the cycle 20 $Tfrm$ every time the frame is decoded. This is because, applied in the present embodiment is the encoding scheme wherein frames occur with the fixed time interval $Tfrm$. In step S512, the CPU 412 determines whether there is any frame to be decoded with the current time interval T_s . If determined No in step S512, that 25 is, if determined that there is no more frame to be decoded by

the current time interval Ts , the procedure exits from the above mentioned loop (steps S509 to S512), and goes to step S513. In step S513, the CPU 412 updates the variable $grid$ to the next $grid$ time. Then, the procedure exits from the function, and returns 5 to step S404 in the main flow (FIG. 13) with a result of TRUE.

[0134] With such algorithm, as shown in FIG. 9, in the terminal 102, the buffer occupancy Sum can be always changed in the vicinity of the value S_{target} , and not exceeding the value S_{target} . Therefore, even if there are several terminals 102 varied in type, 10 and even if the total buffer capacity $Smax$ varies due to the device type, by setting the value S_{target} according to the value $Smax$ in each terminal 102, the buffer will neither overflow nor underflow.

[0135] In this example, as shown in (A) of FIG. 15, packet assembly is performed in a pattern of inserting a plurality of frames into one packet. Alternatively, as (B) of FIG. 15, packet assembly may be performed in a pattern of inserting one frame to one packet. If this is the case, in step S502 of FIG. 14, the second half of the inequality may be changed to

20 $delta + (L+hdr) \leq deltaMax$, and

in step S504, the second half of the equation may be changed to

$delta += (L+hdr)$.

[0136] In the present embodiment, for the sake of simplicity, applied is the encoding scheme wherein frames are occurred with 25 the fixed time interval $Tfrm$. However, if the decoding

calculation algorithm A2 is designed according to the encoding scheme to be applied, for example MPEG-4 video (ISO/IEC 14496-2), the frames are not necessarily occurred with the fixed time intervals. Also, the algorithm is not necessarily the type of handling data on a frame basis, and may be an algorithm of the type handling data on a slice basis, or on a pack basis of the 5 MPEG-1 and MPEG-2 system streams.

[0137] On the other hand, in step S502 of FIG. 14, if the value of S_{target} is changed in the process, the present algorithm 10 instantaneously starts going through packet assembly by targeting the new value of S_{target} after the change. FIGS. 10 and 11 show the change of buffer capacity in such case that the value of S_{target} is changed in the process. In FIG. 10, if the value S_{target} is changed to the value $S_{target2}$ at a time $i=3$ ($S_{target} < S_{target2} \leq S_{max}$), the large amount of frame data is subjected 15 to packet assembly for a while after the change (in the drawing, *delta3* and *delta4*). As a result, the buffer capacity *Sum* reaches the vicinity of the new target value $S_{target2}$.

[0138] As shown in FIG. 11, if the value S_{target} is changed 20 to the value $S_{target3}$ at a time $i=2$ ($S_{target3} < S_{target}$), a little amount (*delta4*) or 0 (*delta3*) of the frame data is assembled to packets. At the same time, the buffer capacity *Sum* is consumed by decoding, therefore the buffer capacity *Sum* also reaches the vicinity of the new target value $S_{target3}$. By utilizing such 25 process, according to the transmission capacity of the network

103 (or the state of the terminal 102 for receiving radio waves), the buffer occupancy in the terminal 102 can be dynamically increased/decreased, realizing the following application.

[0139] In FIG. 7A, considered now is a case where a user 5 carrying a mobile phone 701 (which corresponds to the terminal 102 of FIG. 1) moves along the arrow 702, that is, from the area of the relay station B_1 to the area of the relay station B_2 . As the mobile phone 701 moves, the relay station B_1 has the relay station B_2 take over placing calls to/from the mobile phone 701 10 (handover). In this case, the radio wave intensity of the mobile phone 701 is so changed as the graph shown in FIG. 7B. In the present model, for the sake of simplicity, a point where the intensity changes from high to medium (or from medium to high) is referred to as a threshold value A relevant to the transmission 15 capacity of the network 103, a point from medium to low (or from low to medium) is a threshold value B , and a point from low to out of area (or from out of area to low) is a threshold value C .

[0140] In FIG. 7B, assuming that the user carrying the mobile phone 701 moves by a distance d_1 , and the transmission capacity 20 falls short of the threshold value A . In this case, as shown in FIG. 11, the mobile phone 701 changes the value S_{delay} to a larger value (S_{target2}), and notifies the value to the server 101. This is done to be ready for the possible further decrease in transmission capacity, and thus the server 101 is prompted to go 25 through new packet assembly and transmission, whereby the buffer

in the mobile phone 701 can store data available for longer hours (Δt). In the case that the transmission capacity falls short of the threshold value A but remains yet above the threshold value B , no packet transfer loss is likely to occur. Thus, the
5 transmission speed can be increased as such.

[0141] When the user moves and reaches a distance d_2 , the transmission capacity falls short of the threshold value B , and the packet transfer loss starts occurring. In this case, as shown
10 in FIG. 11, the mobile phone 701 changes the value S_{target} to a smaller value ($S_{target3}$), and notifies the value to the server 101. This is done to be ready for the possible further decrease in transmission capacity, and thus the server 101 is prompted to hold off new packet assembly and transmission. The reason is as follows.

15 [0142] As an example, in the case that the mobile phone 701 applies PHS Internet Access Forum Standard (PIAFS) as the communication mode, if any packet transmission loss is occurred, data retransmission processing is carried out based on the protocol in the PIAFS layer, which is a link layer. The reason
20 for holding off new packet assembly and transmission is that the retransmission processing is inappropriately disturbed thereby.

[0143] When the user moves and reaches a distance d_3 , the transmission capacity falls short of the threshold value C , and at the moment, packet transfer gets difficult. If the user then
25 moves and reaches a distance d_4 , however, the transmission

capacity this time exceeds the threshold value B . As the handover has been already completed, the mobile phone 701 puts back the value $S_{target3}$ back to the original S_{target} this time, and transmits the value to the server 101. In this manner, the data storage, that is, the buffer occupancy Sum is increased. Here, the handover time taken for the PHS, for example, is only a few seconds with the user's normal walking speed. Accordingly, by setting the above-described Δt to 3 to 4 seconds, the handover may not disturb streaming playback in the mobile phone 701.

[0144] Here, as shown in FIG. 11, if the setting value of the S_{target} is changed to a smaller value during data stream distribution, the result in step S502 in the algorithm of FIG. 14 does not become True so soon, and resultantly data on the next frame cannot be sent out. If this happens often, even if the packet is provided to the terminal 102, the presentation time for the frame data in the packet has already passed, and thus the data is of no use. If this is the case, such frame data may be better not to sent out onto the network 103 in consideration of efficiency.

[0145] FIG. 16 is a flowchart showing another example of the function *mkPacket* in step S404 of FIG. 13. The function *mkPacket* of FIG. 16 includes steps S601 and S602, which are provided not to send out data whose presentation time has passed when the server 101 decreases the transmission speed. That is, in the algorithm of FIG. 16, this addition of steps S601 and S602 is the only

difference from the algorithm of FIG. 14, and other steps are identical therebetween. Thus, those steps are each under the same reference numeral. In step S601, the CPU 412 determines whether an *in*th frame data to be currently sent out is not a 0th frame
5 data, and is to be presented later than an *out*th frame data which is regarded as having been decoded in the terminal 102.

[0146] If this result is True, the CPU 412 regards the *in*th frame data can be in time for the presentation time at the terminal, and thus performs data assembly on the data in step S503, and sends
10 it out to the terminal 102. If the result is False, the CPU 412 regards the *in*th frame data did not exist, and in step S602, sets L=0. In this manner, the result in step S502 becomes always True, and at the time of packet assembly in step S503, data frames can
15 be sent out without copying any unwanted frame data. If there is such frame skip, playback performed in the decoder 509 becomes shorter by the time *Tfrm*, and information indicating as such is written in the packets shown in (A) and (B) of FIG. 15 to inform the terminal 102. For example, a header may be provided with a region to which such information about presentation time is
20 written.

[0147] The algorithm shown in FIG. 16 is considered sufficiently effective if the frames are similar in priority (priority level) as the MPEG audio. As to the MPEG video, on the other hand, as described in the Background Art, I frames can each
25 restructure an image of a meaning. However, P and B frames cannot

restructure an image of a meaning without other frames temporally before and after thereto for reference. In this case, when decimating the frames in the algorithm of FIG. 16, the I frames being in time for the presentation time are sent out with higher priority, and skips all of the P and B frames. By doing this, even if the transfer speed of the network 103 is slow, the image of higher quality can be provided to the terminal 102.

[0148] FIG. 17 is a flowchart showing another example of the function *mkPacket* in step S404 of FIG. 13. The function *mkPacket* of FIG. 17 includes steps of S505', S601, S602, S701, and S702 for skipping sending out the data with lower priority and the data of higher priority but already passed by its presentation time when the server 101 decreases the transmission speed. Compared with the algorithm of FIG. 14, the algorithm of FIG. 17 additionally includes steps S601, S602, S701, and S702, and step S505 is replaced by step S505'. Here, step S505' is the one additionally provided with a detection function of a priority *pri* to the function *nextfrm*. Other steps are identical to those in FIGS. 14 and 16, and thus each under the same reference numeral.

[0149] Therefore, compared with FIG. 16, the algorithm of FIG. 17 is additionally provided with steps S701 and S702, and step S505 replaced by step S505'.

[0150] To execute the algorithm of FIG. 17, there needs to include a function of notifying the information (reception state information) indicating the receiving state detected by the

terminal 102 to the server 101. FIG. 18 shows the structure of a server-client system with such function. In FIG. 18, the terminal 102 includes a detection part 801 for detecting the reception state. Between the terminal 102 and the server 101, 5 provided is a notification part 802 for notifying the detected reception state information from the terminal 102 to the server 101. The server 101 is provided with a retention part 803, and retains thus notified reception state information.

[0151] Refer back to FIG. 17 again. Once the function *mkPacket* 10 is called, prior to step S501, step S701 is carried out. In step S701, the server 101 (of the CPU 412) refers to the information retained in the retention part 803, and determines whether the transmission capacity of the network 103 falls short of the threshold value *B*. If determined Yes, a *slowflag* is considered 15 True, otherwise False. Here, the *slowflag* indicates that the transmission speed of the network 103 is slow.

[0152] In step S505', detected is the priority of the next frame. In the following step S702, it is then determined whether the frame 20 data has a higher priority, and the *slowflag* is True or not. If determined Yes, that is, if the *slowflag* is True and the frame has the higher priority, the procedure goes to step S601. In step S601, it is then determined whether the presentation time for the frame has already passed or not. On the other hand, if determined 25 No, the procedure goes to step S602, and L=0 is set. That is, even if the frame seems be in time for the presentation time, the

frame is skipped. The processing hereafter is exactly the same as that in FIGS. 14 and 16.

[0153] As described above, according to the present embodiment, the terminal 102 determines its own buffer capacity and a target 5 value according to the transmission capacity of the network 103.

The terminal 102 also determines a delay time within a range not exceeding a value obtained by dividing the target value by the transmission capacity. Based on these target value and the delay

time determined by the terminal 102, the server 101 controls the 10 transmission speed. Therefore, even if the buffer capacity of

the terminal 102 varies due to the device type, and even if the transmission capacity of the network 103 fluctuates, the transmission speed control can be performed according to the buffer capacity and the transmission capacity. Therefore,

15 streaming playback due to underflow and overflow of the buffer is successfully undisturbed. What is better, the delay time is determined separately from the target value, therefore the streaming playback can be avoided while the waiting time to access a specific frame is reduced.

20 [0154] While the invention has been described in detail, the foregoing description is in all aspects illustrative and not restrictive. It is understood that numerous other modifications and variations can be devised without departing from the scope of the invention.
